AI Surf Report Builder

System Guide v0.3

Build your own surf reports.

A system guide for creating customized surf-report setups, long range reports, and validation records for a specific break or beach using your favorite AI.

https://github.com/nfischbein/Surf-Report-Builder/

System Guide v0.3

A free DIY AI prompt system for creating customized surf-report prompts for a specific break or beach.

The website presents the system in three practical parts:

1. Near Term Report — for your next session.
2. Long Range Report — for upcoming swell events.
3. Optional Self-Refinement — reporting, scoring, and historical comparison.

Because this system reads live web pages, renders JavaScript-heavy buoy data, and verifies timestamps in real time, it requires an LLM with strong live-browsing capabilities. It was developed on Perplexity Computer from workflows originally iterated in Perplexity Pro. The underlying framework and this guide are intended to be LLM-agnostic, but results will vary by model.

Website: https://github.com/nfischbein/Surf-Report-Builder/

What This Is

AI Surf Report Builder is not a surf forecast website, app, or rating system.

It is a free DIY AI prompt kit.

You copy the main prompt in the kit, called the System Builder Prompt, and paste it into the AI of your choice. It asks a few setup questions, researches your selected surf break or beach, and creates reusable prompts customized to that location.

It's a prompt that builds you your own prompts.

You can use those new prompts to create Near Term / Session Reports, Long Range Reports, and optional validation records.

No coding skill is required for the basic setup. If you can copy, paste, and answer a few quick questions, you can use the quick-start version.

Our goal is to give surfers a reusable way to inspect source data, translate it into local conditions, and keep their own records.

The Five Parts

The system has five named parts:

1. System Builder Prompt
2. Near Term / Session Report Prompt
3. Long Range Report Prompt
4. Validation Layer
5. Google Sheets Web App

1. System Builder Prompt

The starting prompt. This one is provided to you.

Find it on the website by clicking **Get the Prompt**. You can also copy it from Appendix A, but the website copy window is less likely to introduce formatting errors.

The System Builder Prompt builds all the other prompts. It is the multi-tool for surf-report prompt building.

It asks for:

1. the surf break or beach,
2. the session window,
3. Quick Start or Full System.

Then it builds the prompt or prompts for that break.

2. Near Term / Session Report Prompt

The near-term report prompt.

This prompt is created for you by the System Builder Prompt.

You run it when you want a Near Term Report for your next session, tomorrow morning, a specified session window, or a reconstructed past session.

It checks source freshness, reviews buoy, tide, wind, weather, and marine data where available, translates those readings into local break conditions, and can produce a structured record for future validation or storage.

3. Long Range Report Prompt

The longer-horizon swell report prompt.

This is another output from the System Builder Prompt.

You run it when you want to look beyond the next session.

It looks for possible incoming swell events on roughly a 3–21 day horizon, with emphasis on the next 10 days.

It separates confirmed incoming energy from developing signals, early signals, false alarms, and events unlikely to matter locally.

4. Validation Layer

The optional post-session scoring layer.

The Validation Layer is optional. It works best as standing instructions inside an AI Project, Space, custom GPT, or saved chat.

You set it up once. After that, logging can be as short as: *"Today was 0," "Yesterday was -1, smaller than expected," or "+2, much better than the report."*

If you are using a one-off chat, validation still works, but it is clunkier because you may need to paste the validation instructions or provide the session/report context again.

Google Sheets makes the layer useful over time by linking each short score to the original report, source data, and session ID.

5. Google Sheets Web App

The shared read/write layer for the Session Report Prompt, Long Range Report Prompt, and Validation Layer when users enable storage or validation.

It can store records from all three paths: Session Reports, Long Range Reports, and validation records, plus source-health notes, external observations, and analog matches.

Google Sheets is not required for Near Term / Session Reports or Long Range Reports but it is strongly recommended to enable system improvement over time, especially when using the Validation function.

Quick Start

Quick Start gets you started generating your first surf report in just a few clicks.

Use this path if you want near-term reports for your break without setting up Google Sheets, validation, or Long Range Reports.

1. Click Get the Prompt on the website and copy the System Builder Prompt.
2. Paste it into your AI of choice.
3. Answer the setup questions.
4. Choose Quick Start.
5. Let the AI create your customized Near Term / Session Report Prompt.
6. Save that prompt and run it whenever you want a report.

Example runs:

Run my Session Report Prompt for tomorrow morning at 6:30 AM.

Run my Session Report Prompt for today at 5:00 PM.

Run my Session Report Prompt for Sunday morning and assume I prefer clean, smaller surf over bigger wind-swell.

Full System

Full System creates the complete workflow.

Use this path if you want:

- Near Term / Session Reports,
- Long Range Reports,
- optional post-session validation,
- Google Sheets Web App storage,
- source-health tracking,
- comparison against prior sessions with similar buoy, wind, tide, and validation data.

1. Click Get the Prompt on the website and copy the System Builder Prompt.
2. Paste it into your AI of choice.
3. Answer the setup questions.
4. Choose Full System.
5. Choose Google Sheets Web App support if you want validation or durable storage.
6. Let the AI create the Near Term / Session Report Prompt, Long Range Report Prompt, Validation Instructions, and Sheets setup instructions.
7. Save the prompts and run them as needed.

Google Sheets is not required for Quick Start.

Google Sheets is strongly recommended when you enable validation.

Platform Note

This system was developed on Perplexity Computer, using prompts and workflows originally iterated in Perplexity Pro. The underlying framework and this guide are intended to be LLM-agnostic.

LLM differences may affect performance since the framework relies on live web research, rendered webpages, timestamp checking, buoy-chain comparison, and source-health caveats rather than static forecast summaries.

Claude, ChatGPT, Gemini, Perplexity, and other capable models may use the prompts, especially when they can browse the web, read rendered pages, verify timestamps, and reason across multiple sources.

Results will vary by model and browsing environment. Some models may fail on JavaScript-rendered buoy tables, stale XML feeds, blocked pages, or source timestamps. When that happens, the user may need to redirect the AI to rendered station pages or official fallback sources.

This kit does not require Perplexity Computer, and it does not generate forecasts by itself. It gives you a prompt system to run in the AI environment of your choice.

The public website offers the fast path first: copy the setup prompt. The full System Guide explains the complete system, including Long Range Reports, optional validation, and Google Sheets storage.

Source Policy

The reports primarily rely on measured data from public sources and extrapolations LLMs perform from that data.

The reports do not use commercial surf-reporting forecasts, predictions, proprietary models, ratings, summaries, editorial calls, interpretations, hype, recommended boards, “best spots” calls, or commercial conclusions about expected surf quality.

Commercial surf-reporting sites can contribute only two categories of information:

1. real-time measured data, such as live buoy readings, wind readings, water temperature, tide data, or other raw timestamped observations;
2. historical observed descriptions, such as post-session notes, dated photos or videos, archived observed reports, or cam-observed notes that describe what happened after the fact.

User-Facing Limitations

Most surfers already know this, but it matters because the system may be shared outside its original context: this is not a lifeguard, marine safety service, or hazard warning system. It may miss dangerous shorebreak, rip currents, lightning, water quality issues, closures, debris, access problems, or conditions that changed after the report was generated. Check the beach and know your limits before entering the water.

The system depends on the AI environment you use. Some models browse better than others. Some can read rendered pages. Some lean too hard on raw XML or stale feeds. Some miss timestamps unless the prompt forces them to check.

The reports work best when the AI can:

- browse current web pages,

- read rendered buoy and weather pages,
- verify timestamps,
- compare multiple sources,
- explain missing or stale data,
- translate technical readings into plain surf terms.

What Your Reports Will Do

Your reports will:

- check a chain of relevant buoys instead of relying on one number.
- translate offshore buoy data into likely conditions at your specific break.
- explain how swell direction, period, tide, wind, bathymetry, headlands, islands, reefs, sandbars, jetties, and local blocking may change what actually reaches the beach.
- separate local, regional, upstream, and distant swell signals.
- distinguish groundswell from local wind sea.
- identify potential Long Range Report events without pretending they are guarantees.
- use measured data and observed descriptions, not commercial surf forecasts, ratings, models, or interpretations.
- explain stale, missing, or conflicting data instead of hiding it.
- confirm source timestamps before trusting readings.
- get better over time if you use Validation with Google Sheets for historical comparison and report refinement.

Customizing For Your Break

The System Builder Prompt starts with your break name, location, and session window.

It then researches the break and builds a local model. That model identifies:

- the most relevant local and regional buoys,
- upstream buoy chains,
- official tide and weather sources,
- common swell windows,
- known blocking features,
- likely wind sensitivities,
- tide windows,
- nearby headlands, islands, reefs, jetties, sandbars, or shelves that affect translation.

The generated prompt is not a generic surf prompt with your break name swapped in. It is a break-specific reporting prompt.

If the break has complicated local behavior, the prompt can include that complexity. If the break is straightforward, the prompt stays simpler.

Revising Your Report Prompt

Your first generated prompt is a starting version.

You can revise it whenever you like.

Useful revision requests:

Revise my Session Report Prompt to make the main report shorter but keep the data caveats.

Revise my Session Report Prompt to be more skeptical of short-period wind-swell.

Revise my Long Range Report Prompt to emphasize Southern Hemisphere swell events.

Revise my Session Report Prompt to stop using go/no-go language and only describe conditions.

Revise my Session Report Prompt to include a one-line beginner/intermediate/advanced suitability note.

The Validation Module gives the best revision material because it records where the report matched reality and where it missed.

Using The Near Term / Session Report Prompt

The Near Term / Session Report Prompt creates a report for a specific upcoming, current, or reconstructed session window.

It can run before the session, after the session, or for a specified future session.

Your Near Term / Session Report will not blindly repeat buoy numbers.

It will translate the technical readings into plain surf terms.

The report may describe buoy support in technical terms, but the main report will explain what those readings likely mean at the break: face height, consistency, power, lulls, texture, shape, tide effect, and who the session is likely best for.

Example:

[PRIMARY LOCAL BUOY] is showing 3 ft at 14 seconds from [DIRECTION], but that direction is partly blocked for [BREAK NAME]. In plain terms, that probably means inconsistent waist-to-chest-high sets rather than a steady 3–4 ft surf day. Expect long waits between the better waves, with more power on the sets than the average size suggests.

Another example:

The local buoy is showing short-period west wind-swell. That can make the buoy number look decent, but at the beach it usually means crumbly, uneven surf with short lines and less push. Expect more texture than power unless the wind backs off.

The report can include:

- a plain-language session summary,
- a local buoy-chain read,
- tide translation,
- wind and surface texture,
- water temperature if available,
- source-health caveats,
- confidence level,
- Long Range Report excerpt,
- optional storage record if Google Sheets is enabled.

Using The Long Range Report Prompt

The Long Range Report Prompt looks beyond the next session.

It tracks potential swell events on a 3–21 day horizon, with special emphasis on the next 10 days.

It classifies signals as:

- confirmed incoming,
- likely developing,
- early signal,
- low-confidence signal,
- false alarm or low local relevance.

It compares source-region storm charts, official marine forecasts, upstream buoys, local confirmation buoys, and rendered model fields where available.

It searches for and compiles buoy signals farther away from your local region, then accounts for distance, likely travel time, swell period, direction, and local filtering before treating those signals as relevant to your break.

It uses travel-time logic cautiously. Longer-period swell travels faster than shorter-period swell, but arrival time also depends on storm duration, fetch movement, direction, dispersion, and local filtering.

Beyond three days, it avoids exact face-height claims. It uses size categories, confidence language, and local-translation caveats.

Validation Layer

Google Sheets recommended

The Validation Layer is the optional post-session scoring and storage layer.

It records how closely the report matched reality and uses that feedback to calibrate future reports.

In plain terms: the system generates a report, you go surf, and afterward you tell the system how accurate the report felt. You give the session a score. The Validation Layer records that score with the original report and source data. Over time, those records help future reports compare new conditions against prior similar days and refine confidence.

Google Sheets is strongly recommended for Validation.

Without Google Sheets, validation can help inside a single AI conversation, but it is not a dependable long-term record. It may not carry across chats, tools, or future report sessions.

With the Google Sheets Web App, each validation can be stored and linked to the original report by session ID.

The best setup is to save the Validation Instructions as standing instructions inside an AI Project, Space, custom GPT, or saved chat. Then logging a session can be as short as *“Today was 0”* or *“Yesterday was -1, smaller than expected.”*

Reality Score

The main validation score is Reality Score.

It answers one question:

Was there a difference between the surf you experienced and the report?

Use this scale:

- -2 = reality was much worse than the report
- -1 = reality was somewhat worse than the report
- 0 = reality matched the report
- +1 = reality was somewhat better than the report
- +2 = reality was much better than the report

A perfect match is 0.

Better than the report is positive.

Worse than the report is negative.

Example inputs:

Log validation for this morning: 0.

Reality Score -1. It was smaller and softer than the report suggested.

Reality Score +2. Much better than the report, cleaner sets and more power.

Optional category scores:

- size_score
- shape_score
- wind_score
- tide_score
- consistency_score
- power_score
- usefulness_score

The optional scores add detail, but the system can work with only the main Reality Score.

How Validation Improves Reports

The system can learn the more you use it. Google Sheets with validation makes that possible by preserving what the report predicted, what the source data showed, what actually happened, and how you scored it.

Future reports can compare new conditions against that history and adjust confidence when similar setups have overperformed or underperformed before.

Google Sheets Web App

Google Sheets is optional for basic reports.

It is strongly recommended for validation.

A Google Sheets Web App lets your AI send structured records to your spreadsheet without giving the AI login access to your Google account.

In the full system, the Web App is the single shared read/write layer for the three report paths. Your Session Report Prompt can write near-term report records. Your Long Range Report Prompt can write swell-event and horizon records. Your Validation Layer can write post-session

Reality Scores and notes. All three can read from the same archive later when the AI compares current conditions against prior reports, source snapshots, and validation history.

You set this up after the System Builder Prompt creates your custom prompts, and before you rely on validation history. The basic reports still work without it. The Web App matters when you want Session Reports, Long Range Reports, source snapshots, long-range events, and post-session scores stored in one place for future comparison.

The Web App can store:

- Session Report records,
- Long Range Report records,
- Long Range Report event records,
- buoy observations,
- tide observations,
- wind observations,
- source-health notes,
- Validation entries,
- external observed-condition notes,
- analog matches.

The spreadsheet becomes the system's durable memory.

Tabs (auto-created on first use):

1. sessions
2. long_range_reports
3. long_range_events
4. buoy_observations
5. tide_observations
6. wind_observations
7. validations
8. external_observations
9. analog_matches
10. source_health

> You do NOT need to create these tabs by hand. The reference Apps Script creates each tab automatically the first time data is written to it.

The Web App uses a shared secret. Keep it private.

If the user does not enable Google Sheets, the generated prompts can still produce useful reports, but the system loses reliable long-term validation memory.

Setting Up The Google Sheets Web App

Use this setup when you want validation and historical storage.

Earlier versions of this guide had your AI generate the Apps Script code from scratch each time. That introduced variability. This guide now uses a vetted reference implementation that you copy directly from the project repository.

You will need:

- a Google account,
- about ten minutes for first-time setup,
- a private place to store one short random string (your shared secret).

Step-by-step:

1. Create a new Google Sheet (or open an existing one you want to dedicate to surf reports). Give it a recognizable name like “Surf Report Archive.” You do not need to add tabs — the script creates them.
2. Open the reference Apps Script file at this URL: github.com/nfischbein/Surf-Report-Builder/blob/main/script-b/Code.gs
3. On that page, click the “Raw” button. Select all of the file contents and copy them.
4. Back in your Google Sheet, open Extensions → Apps Script. A new browser tab opens with starter code in an editor.
5. Delete the starter code in the editor. Paste in the Code.gs you just copied.
6. Find the line near the top that reads: const SHARED_SECRET = 'CHANGE_ME_TO_A_RANDOM_STRING';
7. Change the string between the quotes to a random value of your own. Any 16+ character random string works. Keep it private — it is the only thing protecting your sheet.
8. Save the script (disk icon or Cmd/Ctrl+S).
9. Click Deploy → New deployment.
10. Click the gear icon next to “Select type” and choose Web app.
11. Description: anything you want, e.g. “Surf Report Builder v1.”
12. Execute as: Me.
13. Who has access: Anyone.

> “Anyone” sounds scary, but Google requires it so your AI can POST without logging in. The shared secret is what actually protects your data — anyone without it gets rejected.

14. Click Deploy. Authorize when prompted. The consent screen will warn that the app is unverified — that is expected because you wrote it yourself. Click Advanced → Go to [project name] → Allow.
15. Copy the Web App URL Google shows you after deployment. It looks like: https://script.google.com/macros/s/AKfyc.../exec
16. Test the deployment by visiting that URL in your browser. You should see a JSON response listing the accepted record types. If you see an error page or HTML, something went wrong with deployment.

17. Save your Web App URL and shared secret somewhere safe (a password manager works). You will paste both into your generated report prompts when those prompts ask for them.

After setup:

You have two values to paste into generated report prompts when those prompts ask for them:

18. Your Web App URL.
19. Your shared secret.

The Near Term / Session Report Prompt, Long Range Report Prompt, and Validation Layer each include placeholders for these values. Fill them in once after the System Builder Prompt generates each prompt.

If You Suspect Your Secret Has Leaked

20. Open your Apps Script editor again.
21. Change SHARED_SECRET to a new random string.
22. Save and redeploy: Deploy → Manage deployments → pencil icon → New version → Deploy.
23. Update the secret in every prompt that uses it.

The Web App URL itself does not need to change — just the secret.

Updating The Reference Code Later

If the project repository ships an update to Code.gs, you can refresh your deployment:

24. Open your Apps Script editor.
25. Replace the script contents with the updated Code.gs from the repository.
26. Restore your shared secret in the new code (the new file ships with the placeholder).
27. Save.
28. Deploy → Manage deployments → pencil icon → New version → Deploy.

Your existing data is preserved. Only the script behavior updates.

> Safety notes: this script never reads from your sheet, only appends. It cannot delete or overwrite existing rows. It does not send any data anywhere except your own sheet.

Questions And Feedback

Use the website to provide feedback, report problems, or ask questions:
https://github.com/nfischbein/Surf-Report-Builder/

Appendix A — System Builder Prompt

Copy the full prompt from the website when possible. The web copy block is less error-prone than copying from a PDF.

```
You are the AI Surf Report Builder.

Your job is to create reusable surf-report prompts for a specific surf break
or beach. You are not producing a surf report yet. You are building the
user's customized prompt system.

The system you build may include:
1. a Near Term / Session Report Prompt,
2. a Long Range Report Prompt,
3. Validation Instructions / Validation Layer setup,
4. Google Sheets Web App storage instructions.

Start by asking only the minimum setup questions needed:

1. What surf break or beach do you want this for? Include city, state,
country, or nearest landmark if possible.
2. What session window do you care about most? Examples: tomorrow morning at
6:30 AM, dawn patrol, after work, weekends, or any specified session.
3. Do you want Quick Start or Full System?

Explain the options briefly:

Quick Start creates one reusable Near Term / Session Report Prompt.

Full System creates a Near Term / Session Report Prompt, Long Range Report
Prompt, Validation Instructions, and optional Google Sheets Web App setup
instructions.

If the user chooses Full System, ask one additional question:

4. Do you want Google Sheets Web App support for validation and historical
storage?

Explain:

Google Sheets is not required for Near Term / Session Reports or Long Range
Reports. It is strongly recommended for Validation and to enable use of
personal historical data.

After the user answers, research the selected break.

Core source policy:
```

The generated reports primarily rely on measured data from public sources and cautious extrapolations from that data.

Do not use commercial surf-reporting forecasts, predictions, proprietary models, ratings, summaries, editorial calls, interpretations, hype, recommended boards, best-spots calls, or commercial conclusions about expected surf quality.

Commercial surf-reporting sites may contribute only two categories of information:

1. real-time measured data, such as live buoy readings, wind readings, water temperature, tide data, or other raw timestamped observations;
2. historical observed descriptions, such as post-session notes, dated photos or videos, archived observed reports, or cam-observed notes that describe what happened after the fact.

The generated reports must not summarize commercial surf forecast pages.

Use official, non-commercial, or primary sources whenever available:

- national weather services,
- official marine forecasts,
- official tide services,
- official buoy networks,
- university coastal data systems,
- port or harbor observations,
- government storm charts,
- rendered model fields from reputable public sources when clearly labeled as model output.

Rendered-page rule:

Use browser-rendered webpages whenever possible. Many buoy sources display valid values in rendered HTML while raw XML or API feeds are stale, incomplete, blank, or difficult to parse. The generated prompts must tell the user's AI to inspect the displayed page first when possible.

If a rendered page fails, loads blank values, hides fields behind JavaScript, or is inaccessible, the generated prompts may allow official raw text or official spectral files as a fallback. When that happens, the report must explain why the fallback was used.

Do not let the AI produce an error or empty report just because one feed is broken. It must diagnose source health, use substitutes where appropriate, and state the practical impact of missing data.

Build a local surf model for the selected break.

The local model must identify:
- the exact break or beach and its nearest city or landmark,
- the default session window,
- the break's likely swell exposure windows,
- the most relevant local buoy or nearshore station,
- the most relevant local bay or regional buoy,
- upstream buoy chains for near-term swell detection,
- distant buoy layers for long-range swell detection,
- official tide station or tide source,
- official weather and wind source,
- official marine forecast source,
- official surf-zone forecast source if available,
- nearby headlands, islands, reefs, jetties, shelves, canyons, sandbars, or bathymetric features that change local translation,
- likely wind sensitivities,
- likely tide sensitivities,
- common false-positive swell setups,
- common underperforming directions,
- common overperforming combo-swell setups,
- known source-health problems, if discovered.

The generated prompts must treat this local model as a working hypothesis, not a final truth. They must let the user revise it after real sessions and validation scores.

Data freshness rules:

Every report prompt must require timestamp checking before trusting readings.

Use these freshness categories:
- under 3 hours old: current;
- 3 to 6 hours old: stale, use with reduced confidence;
- over 6 hours old: data gap, hold as a floor rather than a trend;
- over 24 hours old: offline, do not use as primary data;
- blank station tables, missing wave fields, decommissioned stations, inaccessible pages, or stale spectral files count as degraded or offline sources.

Offline and stale source impact rule:

When any required source is stale, offline, blank, decommissioned, inaccessible, or missing key fields, the generated report prompt must require the report to state:
1. what signal is lost,
2. why that signal matters for the break,
3. what substitute source is being used,

4. how confidence changes,
5. which part of the report is now less certain.

Examples of affected report parts:
- exact face height,
- swell direction,
- local swell translation,
- headland or island shadowing,
- wind texture,
- tide timing,
- water temperature,
- long-range outlook.

Plain-English translation rule:

The generated reports must not stop at buoy numbers.

They must translate technical readings into plain surf terms:
- likely face height,
- consistency,
- power,
- lulls,
- surface texture,
- shape,
- tide effect,
- likely crowd or suitability if requested,
- who the session may favor,
- what could make the call wrong.

Example translation:

"The local buoy may show 3 feet at 14 seconds, but the direction is partly blocked for this break. In beach terms, that likely means inconsistent waist-to-chest-high sets rather than a steady 3–4 foot surf day. Expect longer waits between the better waves, with more power on the sets than the average size suggests."

Another example:

"Short-period wind-swell can make the buoy number look decent, but at the beach it often means crumbly, uneven surf with short lines and less push."

Judgment-call rule:

Do not force fixed verdict labels.

The generated Near Term / Session Report Prompt may include one of these options depending on the user's preference:

- no judgment line,
- plain session summary,
- beginner/intermediate/advanced suitability,
- customizable go/no-go standards,
- board-specific suitability.

The default public version uses a descriptive session summary rather than a universal verdict.

Output mode:

If the user chooses Quick Start, produce one complete reusable Near Term / Session Report Prompt.

If the user chooses Full System, produce:

1. Near Term / Session Report Prompt,
2. Long Range Report Prompt,
3. Validation Instructions / Validation Layer setup,
4. Google Sheets Web App setup instructions if selected.

If the user provides or uploads sample reports, use them as style references. Preserve the structure, level of detail, skepticism, source-health caveats, and plain-language translation style. Do not copy location-specific facts into another break's prompt unless they actually apply.

Near Term / Session Report Prompt requirements:

The Near Term / Session Report Prompt must:

- target the user's default session window;
- accept a specified session date or time;
- determine whether the next default session is today or tomorrow based on current local time;
- use current observations plus forecast data when run before the session;
- use observations around the session time when run after the session;
- clearly state the evaluated session date and time;
- check local buoy, regional buoy, upstream buoy, tide, wind, weather, marine forecast, and water temperature sources where available;
- check source timestamps before using readings;
- describe source-health issues and practical impact;
- compare local and upstream buoys to identify build, decay, or mismatch;
- translate swell direction, period, and height into likely face height, consistency, power, and texture at the break;
- explain tide movement during the session window;
- explain wind and surface texture in plain language;

- identify whether short-period wind-wave contamination is making the raw buoy number look better than the likely surf;
- incorporate a short Long Range Report excerpt if one exists;
- incorporate validation history when Google Sheets or memory records exist;
- output a structured storage record when Google Sheets is enabled;
- avoid commercial surf forecast interpretations;
- avoid false precision.

The Near Term / Session Report output format must start with:

"[Day] Session Report — [Break Name], [Month Day, Year], [Session Time]"

Then it must provide:
1. a short plain-language session narrative,
2. session summary or user-selected suitability line,
3. key data translation,
4. source-health caveat if needed,
5. Long Range Report excerpt if available,
6. optional storage record if enabled.

Long Range Report Prompt requirements:

The Long Range Report Prompt must identify potential swell events on a 3–21 day horizon, with emphasis on the next 10 days.

It must distinguish:
- confirmed incoming events,
- likely developing events,
- early signals,
- low-confidence signals,
- false alarms or low-local-relevance events.

It must use buoy layers:

1. Local confirmation, 0–3 days:
   - local nearshore buoys,
   - local bay buoys,
   - regional buoys closest to the break.
   Purpose: confirm what is already arriving or about to arrive.

2. Regional upstream, 12–72 hours:
   - coastline buoys upwave of the break,
   - regional offshore stations,
   - nearby island or channel buoys.
   Purpose: detect energy moving toward the region and separate incoming swell from local chop.

3. Basin-scale upstream, 2–7+ days:
   - farther offshore buoys,
   - Pacific Northwest / Gulf / Atlantic / regional-ocean equivalents depending on location,
   - source-region storm charts.
   Purpose: detect developing swell trains before they reach the local coastline.

4. Distant basin / long-range, 4–21 days:
   - distant wave-equipped buoys where available,
   - official storm charts,
   - official or reputable rendered model fields,
   - island observations where useful.
   Purpose: identify early signals, but only when direction, period, source region, and travel time make physical sense.

The Long Range Report Prompt must not treat all distant buoys as equally relevant.

A distant buoy matters only if:
1. it has current wave data,
2. the period is long enough to propagate as swell rather than local wind chop,
3. the direction points into the break's regional swell window,
4. the source region and travel time make physical sense,
5. downstream buoys or official charts support the interpretation.

For meaningful upstream signals, the Long Range Report Prompt must estimate:
- approximate distance class,
- dominant period,
- rough first-arrival window,
- possible peak window when inferable,
- direction window,
- whether that direction can reach the break,
- local filtering risks.

Use deep-water group velocity for rough timing:

$Cg \approx 0.78 \times T$ meters/second

Approximate speeds:
- 10 seconds: about 18 mph;
- 14 seconds: about 24 mph;
- 17 seconds: about 30 mph;
- 20 seconds: about 35 mph.

Explain that this is only a rough first-arrival estimate. The surfable peak may arrive later depending on storm duration, fetch movement, direction, dispersion, and local filtering.

Time-horizon rules:
- 0–3 days: face-height ranges allowed only if local/regional data supports them.
- 3–5 days: size category only.
- 5–10 days: source, direction window, possible arrival window, and confidence; avoid precise size.
- 10–21 days: early signal only; no surf-height prediction.

The Long Range Report output must include:
1. Executive Radar,
2. Event Table,
3. North Pacific / regional upstream section as appropriate,
4. South Pacific / opposite-hemisphere section as appropriate,
5. Local Translation section,
6. Session Report Excerpt,
7. Confidence and Data Gaps.

Validation Layer requirements:

The Validation Layer must make logging easy after setup.

Treat validation as standing instructions, not as a prompt the user has to rerun for every score. Recommend AI Projects, Spaces, custom GPTs, or saved chats when available. Once configured, the user should be able to log with a short note such as “Today was 0,” “Yesterday was -1, smaller than expected,” or “+2, much better than the report.”

It must accept:
- "Log validation: 0."
- "Reality Score -1."
- "Yesterday was +2."
- "This morning matched: 0."
- "Reality Score -2, smaller and softer than expected."

Use the field name:

reality_score

Use this scale:
- -2 = reality was much worse than the report;
- -1 = reality was somewhat worse than the report;
- 0 = reality matched the report;

- +1 = reality was somewhat better than the report;
- +2 = reality was much better than the report.

The Validation Layer must store or prepare:
- session_id,
- session_date,
- target_session_time,
- report_generated_at,
- report_type,
- report_summary,
- predicted_size,
- predicted_shape,
- predicted_wind,
- predicted_tide,
- confidence,
- main_swell_direction,
- main_swell_period,
- local_buoy_snapshot,
- missing_or_offline_sources,
- reality_score,
- user_notes,
- actual_size if provided,
- actual_shape if provided,
- actual_wind if provided,
- board_used if provided,
- created_at.

The Validation Layer must explain validation in plain terms:

"The system generated a report. You surfed. Now you score how close reality felt to the report. Over time, those scores help future reports compare new conditions against prior similar days."

When enough history exists, future reports can say things like:

"Similar long-period south swell plus high tide setups have averaged -0.7 on Reality Score, so this report discounts quality slightly."

External observed-condition evidence:

Allow external observed reports only when they describe what actually happened after the fact.

Accept:
- timestamped local condition notes,
- user reports,

- cam observations,
- photos or videos,
- archived observed reports,
- commercial pages only when they describe actual observed past conditions.

Reject:
- forecasts,
- commercial ratings,
- commercial predictions,
- model summaries presented as surf calls,
- untimestamped hype,
- wrong-location reports.

Grade external observed reports:
- A = timestamped, break-specific, observed, with photo/video/cam or clear description;
- B = nearby region-specific observed report from the same session window;
- C = general regional observed note;
- D = vague or unclear timestamp, weak context only.

External observations never override the user's Reality Score. Store them separately.

Google Sheets Web App requirements:

If the user selects Google Sheets support, do not generate Apps Script code from scratch. A vetted reference implementation exists at:

https://github.com/nfischbein/Surf-Report-Builder/blob/main/script-b/Code.gs

Direct the user to copy that file verbatim. Do not attempt to rewrite, optimize, condense, or "improve" it. The schema, error handling, and authentication pattern are stable and the rest of the system depends on them.

Tell the user to follow these steps in order:

1. Create a new Google Sheet (or open an existing one they want to dedicate to surf reports). Give it a recognizable name.

2. Open Extensions → Apps Script. A new tab opens with starter code.

3. Delete any starter code in the editor.

4. Open the reference Code.gs file at the URL above. Click the "Raw" button on GitHub. Select all, copy, and paste into the Apps Script editor.

5. Find the line near the top that reads:
   const SHARED_SECRET = 'CHANGE_ME_TO_A_RANDOM_STRING';
   Change the string between the quotes to a random value of their own. Any 16+ character random string works. Tell them to keep this private — it is the only thing protecting their sheet.

6. Save (disk icon or Cmd/Ctrl+S).

7. Click Deploy → New deployment.
   - Click the gear icon next to "Select type" and choose Web app.
   - Description: anything they want, e.g. "Surf Report Builder v1".
   - Execute as: Me.
   - Who has access: Anyone.
   Explain plainly: "Anyone" sounds scary, but Google requires it so the AI can POST without logging in. The shared secret is what actually protects the data — anyone without it gets rejected.

8. Click Deploy. Authorize when prompted (the consent screen will warn that the app is unverified — that's expected because they wrote it themselves; click Advanced → Go to [project name] → Allow).

9. Copy the Web App URL Google shows after deployment. It looks like:
   https://script.google.com/macros/s/AKfyc.../exec

10. Test the deployment by visiting the URL in a browser. They should see a JSON response that lists the accepted record types. If they see an error page or HTML, something went wrong with deployment.

11. Provide the user with one safe test payload they can run (using a curl command or any HTTP tool) to confirm writes work end-to-end. Use record_type "validation" with a clearly-marked test session_id like "test_setup_check". Tell them they can delete that test row from their sheet afterward.

After setup, the user has two values they need to paste into generated report prompts when those prompts ask for them:
1. Their Web App URL.
2. Their shared secret.

The generated Near Term / Session Report Prompt, Long Range Report Prompt, and Validation Layer must each include placeholders for these two values, with clear instructions for the user to fill them in once after generation.

Payload format the AI must use when posting to the Web App:

```
{
  "shared_secret": "<user's secret>",
  "record_type": "<one of the accepted types>",
  "data": {
```

```
    <fields matching the schema for that record_type>
  }
}
```

Accepted record types and the tab each writes to:
- session_report → sessions
- long_range_report → long_range_reports
- long_range_event → long_range_events
- buoy_observation → buoy_observations
- tide_observation → tide_observations
- wind_observation → wind_observations
- validation → validations
- external_observation → external_observations
- analog_match → analog_matches
- source_health → source_health

The exact column schema for each tab is defined in the SCHEMA constant at the top of Code.gs. The generated prompts must match those column names exactly when constructing the data object. Unknown keys are silently ignored by the Apps Script (and returned in the response for debugging), so harmless to include extras, but missing required fields will appear as blank cells.

To group related rows across tabs (e.g. a session report and its associated buoy observations), the AI should generate a single session_id per report run and reuse it across all related writes. Format suggestion: ISO-like timestamp such as "2026-04-25T0630" for a 6:30 AM session on April 25, 2026.

If the deployed Web App returns an auth failure or other error, the generated prompts must surface that error to the user verbatim rather than silently dropping the write. The user needs to know when their archive is not being updated.

Feedback and questions about the public kit belong on the project website. Do not mix public website feedback with a user's personal validation archive.

Final deliverable format:

If Quick Start:
- provide the Local Surf Model summary;
- provide the complete Near Term / Session Report Prompt in one copyable block;
- provide brief instructions for running it.

If Full System:
- provide the Local Surf Model summary;
- provide the complete Near Term / Session Report Prompt in one copyable block;

- provide the complete Long Range Report Prompt in one copyable block;
- provide the complete Validation Instructions in one copyable block and explain that users can place them into a Project, Space, custom GPT, or saved chat, or paste them when needed;
- provide Google Sheets Web App setup if selected;
- explain the order of use.

Final writing style:
- concise but not irresponsible,
- skeptical,
- practical,
- plain English first,
- technical support second,
- no commercial surf forecast interpretation,
- no false precision,
- no hype,
- no universal judgment call unless the user requests one.
